Abstract. Some CP stars have recently been discovered by Catalano et al. (1991) to be variable also in the near infrared, although with smaller amplitudes than in the visible. Hence an observational campaign was started in which the infrared light variability of a number of CP2 and CP4 stars has been investigated at the ESO-La Silla Observatory in the bands *J*, *H*, and *K*. As a general result, infrared variations show the same behavior in all three filters but amplitudes are smaller than in the visible.

Key words: Stars: chemically peculiar — Stars: variables: other

1. Introduction

Kroll et al. (1987) showed that the near infrared fluxes and colors of Chemically Peculiar stars (or CP stars, according to Preston's (1974) scheme), when compared to a black body, are normal, like that of early main sequence stars. IRAS data could even prove that the normality of IR fluxes is guaranteed to at least 25μ (Kroll 1987): only two CP4 stars showed flux excesses longward of 60μ , showing cold circumstellar material, which is not uncommon among early B stars. Moreover Leone & Catalano (1991) have shown that the solar composition Kurucz model atmospheres, which are used to fit the spectra of CP stars from $\lambda 5500$ to $\lambda 16500$ Å, give a fair representation of the overall flux distribution, with the exception of the Balmer region, where CP stars appear generally brighter than normal, this excess being just a few percent of the total flux.

However, in spite of this normal infrared behavior, peculiar abundances and/or magnetic fields seem to affect the near infrared too; in fact, Catalano et al. (1991) have shown that, out of the eight CP stars monitored throughout their rotational periods, at least six are variable in the near infrared, although with smaller amplitudes than in the visible. This unexpected result led us to start an observational campaign aimed at searching for infrared variability and also to better understand the origin of the light variability, which is one of the outstanding observational aspects of these stars.

2. Observations

The observations have been carried out in the near IR bands J, H, and K at the 1-m photometric telescope at ESO, La Silla, Chile, using an InSb detector cooled with liquid nitrogen. A detailed description of the ESO infrared photometers can be found in Bouchet (1989).

The data have been collected during several observing runs from July 1986 through January 1993. All program stars were measured relative to closeby comparisons, which were chosen to have as similar color and brightness as possible. The integration times, the number of cycles, and the desired r.m.s. accuracy in the mean level were optimized to get a 2% maximum error in the observations: the resulting accuracy in the final reduced data is typically 0.006 mag. ESO standard software was used for all reduction steps. Magnitudes in the standard IR system have also been obtained by observing suitable standard stars from the ESO list (Bouchet et al. 1991).

The adopted ephemeris elements of the infrared light curves for the programme stars have been mainly taken from Catalano & Renson (1984, 1988, 1997), Catalano, Renson & Leone (1991, 1993), and references therein. The results concerning the SrCrEu and Si et al. stars have been published elsewhere (Catalano et al. 1997, 1998).

3. Discussion and conclusions

Near infrared variability has been found to be present in the large majority of the CP2 stars studied. The typical trend of CP2 stars to present smaller amplitude light variations at increasing wavelength is confirmed: the amplitudes in the near infrared are smaller than in the visible. In most cases the variations have

been found to show very similar behavior and in phase with each other in all filters.

In a previous paper (Catalano et al. 1991) we investigated the effects of high metallicity at the near infrared wavelengths and showed that a Kurucz model atmosphere with a metal content ten times the solar one could explain a three percent variation in the near infrared brightness, which is the typically observed value.

The influence of the magnetic field in the atmosphere structure has been quantitatively discussed by some authors in some particular configurations, however the most general approach has been carried out by Stępień (1978) who showed that, according to the direction of the toroidal electric currents in the outermost layers, the star's shape can be prolate or oblate with respect to the magnetic axis: the differences between the polar and equatorial values of the radius being up to 3%. The results obtained by Stępień lend support to a distorted figure of the star up to a few percent and to small variations (2-3%) of the effective temperature over the surface, which in some cases, can contribute to the observed light variations. While this explanation is not valid as far as it concerns the visible light variations of many CP stars, because of the different behaviours presented by the u , v , b , and y curves, it cannot be excluded that the non-spherical shape of the star as seen at the infrared wavelengths could contribute to the observed variability, since the magnetic pressure importance increases in the outer layers.

After completing the analysis of our infrared data, we hope to be able to disentangle the relative contributions of these two mechanisms from the study of the phase relation between the magnetic field and infrared variations.
