The recently developed method of Doppler-Zeeman mapping of magnetic CP stars (Vasilchenko et al.,1996, hereafter referenced as V.S.K., and also the contribution to this volume) confirmed its efficiency and robustness not only for model tests but also in the case of a real star.

The method was used for mapping Babcock's star HD 215441, wich has the strongest known magnetic field and resolved Zeeman components in the lines of its spectra (Khokhlova et al., 1997, hereafter referenced as K.V.S).

We used the spectra of the CP star HD 215441 kindly given to us by Prof. Landstreet and which he had obtained with the coudé-spectrograph of the 3.5m Canada-France-Hawaii telescope and a Reticon detector. The spectral resolution was 0.1 Å and the signal-to-noise ratio $S/N \geq 200$. We did not have polarization data at our disposal, but completely resolved π and σ components are practically equivalent to measured Stokes V parameter (except for the sign of the polarization and hence the lack of possibility to determine the sign of the magnetic-dipole vector). We assumed the signs of poles obtained in previous studies of this star (Landstreet et al., 1989).

Abundance maps for Si, Ti, Cr and Fe obtained from different lines of each element coincide very well. The magnetic field configurations obtained from 8 lines of four different elements were identical. They have been reliably determined for the star's surface facing the observer. The maps are shown in Fig. 1.

The magnetic field configuration is well fitted by a shifted-dipole model with dipole parameters $H_D = (21.3 \pm 1.9)$ kG and shift $a = (0.12 \pm 0.024)R^*$. The positive polar field $H_{p+} = +(39.0 \pm 2.0)$ kG and the negative $H_{p-} = -(44.0 \pm 9.0)$ kG. The local magnetic vectors were calculated for each point of the stellar surface. The position of maximum surface magnetic field H_S on the visible hemisphere is determined to be $L = (5°.6 \pm 6°.8)$, $\varphi = (63° \pm 7°.8)$ and the strength of the visible magnetic pole is $max(H_S) = (42.3 \pm 2.9)$ kG.

A comparison of magnetic and chemical maps definitely shows that at the visible magnetic pole most elements are strongly (Si, Cr) or slightly (Ti) under-

abundant but Fe is strongly overabundant. A large-scale ring structure around the magnetic pole is clearly seen on abundance maps (Fig. 1). The complete ring with strong Si overabundance is situated at low magnetic latitudes but not exactly on the magnetic equator. A strongly overabundant spot of Ti and of Cr is located on the background of a less overabundant ring, which is at the same place as the strong Si (and faint Fe) ring. Its location is particular, being not only near the magnetic equator, but also on the rotational equator.

The possibility of such a detailed and reliable comparison between magnetic field structure and abundance maps for magnetic CP stars is demonstrated for the first time in this study. The mapping became possible with a modest computer facility (PC Pentium) thanks to the method we used: analytic approximation of local line profiles and series expansion of the second order of multipole magnetic field geometry. The magnetic field of this star could be well approximated by a shifted dipole as well as by centered dipole and quadrupole.

We had to assume that the atmospheric model parameters T_{eff} and $\log g$ are constant over the surface of the star but this may not be true in reality. Due to evidently strong chemical inhomogeneities seen in Fig. 1, one may expect different metallicities at different places. But it is well known, that Kurucz's models with different metallicities may provide big differences in computed line intensities. For our case it is demonstrated by Fig. 4 of K.V.S..

We cannot tell as yet, which element's abnormal abundance is most efficient to produce such effects, because Kurucz's metallicity is a scaled Solar abundance. One may only guess that C, N, O, Si, as most abundant elements, may play a dominant role as electron donors at the temperature of this star ($T_{\mathrm{eff}} = 16000$) K, and also Fe, which is abundant and has many lines to contribute to the backwarming effect.

In general, the strict approach to solve the inverse problem of Doppler-Zeeman mapping requires iterations to be built as follows:

At each step of minimization of residual Functional, one uses the values of local abundances, local atmosphere models and local magnetic field vectors all obtained at the preceding step, and then performs the integration of the transfer equation to compute local Stokes profiles and local surface brightness, integrates them over the visible surface to calculate the "observed" profile and the residual Functional for the next step of minimization. Obtaining the new set of local abundances, one should make computations of new local atmosphere models. Now the "loop" is closed and a new iteration may be started.

Keeping in mind that a dense coordinate grid on the stellar surface is desirable and that local abundances of more than one element are needed to be determined to make corrections to local atmosphere models at each iteration, the amount of time required for the strict solution by the above scheme is huge and unrealistic with the methods known and the available computers at the present time.

The way we compute local Stokes profiles as a corrected analytic solution of transfer equations (as is described in detail in V.S.K) opens the possibility to
Phase 0　　　　　Phase 180

Fe

Cr

Si

Ti

solve the problem in a realistic time without serious loss of precision. It seems
that one may not blame this method of local profiles computing for having not
enough precision, until the problem of determining correct local atmosphere
models is solved. It is impossible to guarantee better local profiles by strict
numerical integration of the transfer equation only, without solving this problem.
We have also to mention the problem of vertical stratification of abundances in
CP stars, predicted by theoreticians (Babel & Mishaud, 1991) and investigated
by observers (Babel, 1994; Romanyuk et al., 1992, and other attempts). If this
stratification exists, further complications appear.

Returning to Fig. 1, one may see that Fe is overabundant near the magnetic
pole. If a "metallicity" effect is determined by iron abundance, the iron spot
must be hotter and there must be a bright spot there. Indeed, it is known that
the maximum of the almost sinusoidal lightcurve of HD 215441 occurs at zero
phase.

One may expect that the local intensity of Ti II and Cr II lines should decrease
in a hot spot due to the second ionisation of these ions, and it is really the case,
as Fig. 1 shows. But one cannot tell, whether this is the only reason, or whether
real underabundances of Ti and Cr also exist.

For Si III lines the temperature change has the reverse sign, their inten-
sity should increase with increasing metallicity (increasing temperature in line-
forming layers). But they decrease! This may be interpreted only as a real un-
derabundance of Si near the magnetic pole.

A more detailed study of HD 215441 from spectra covering a wider wave-
length range, involving more lines and other elements and also including polar-
ization spectra, is urgently needed and seems to be very promising.
